In practice, direct current (DC) is used in an electrocoagulation processes. In this case, an impermeable oxide layer may form on the cathode as well as corrosion formation on the anode due to oxidation. This prevents the effective current transfer between the anode and cathode, so the efficiency of electrocoagulation processes declines. These disadvantages of DC have been diminished by adopting alternating current (AC) in electrocoagulation processes. The main objective of this study is to investigate the effects of AC and DC on the removal of cadmium from water using aluminum alloy as anode and cathode. The results showed that the removal efficiency of 97.5 and 96.2% with the energy consumption of 0.454 and 1.002 kWh l⁻¹ was achieved at a current density of 0.2 A dm⁻² and pH of 7.0 using aluminum alloy as electrodes using AC and DC, respectively. For both AC and DC, the adsorption of cadmium was preferably fitting Langmuir adsorption isotherm, the adsorption process follows second order kinetics and the temperature studies showed that adsorption was exothermic and spontaneous in nature.

1. Introduction

Heavy metal pollution has become one of the most serious environmental problems today. The treatment of heavy metals is of special concern due to their recalcitrance and persistence in the environment. Unlike organic contaminants, heavy metals are not biodegradable and tend to accumulate in living organisms and many heavy metal ions are known to be toxic or carcinogenic. Toxic heavy metals of particular concern in treatment of industrial wastewaters include zinc, copper, nickel, mercury, cadmium, lead and chromium. Cadmium is one of the most toxic non-essential heavy metals present in the environment, even at low concentrations. Elevated level of cadmium ions arise from a variety of sources such as wastewater from metal plating industries, nickel–cadmium batteries, phosphate fertilizer, mining, pigments, stabilizers, alloys, petroleum refining, welding and pulp industries [1–3]. Cadmium poisoning includes kidney damage [4], lung insufficiency, cancer; it changes the constitution of bone, liver and blood [5]. Cadmium accumulated in the rice crops, it developed Itai-Itai disease and renal abnormalities including proteinuria and glucosuria. Cadmium containing compounds are known as carcinogens [6,7]. The drinking water guideline value is 0.005 mg/L [8].

Conventional methods for removing cadmium from water include ion exchange, reverse osmosis, co-precipitation, coagulation, complexation, solvent extraction, electrochemical treatment and adsorption [9–25]. Physical methods like ion exchange, reverse osmosis and electrodialysis have proven to be either too expensive or inefficient to remove cadmium from water. At present, chemical treatments are not used due to disadvantages like high costs of maintenance, problems of sludge handling and its disposal, and neutralization of the effluent [26]. The cadmium removal from water by adsorption using different materials has also been explored. The major disadvantages of this studied adsorbent are low efficiency and high cost. Recent research has demonstrated that electrocoagulation offers an attractive alternative to above-mentioned traditional methods for treating water [27]. In this process anodic dissolution of metal electrode takes place with the evolution of hydrogen gas at the cathode [28]. Electrochemically generated metallic ions from the anode can undergo hydrolysis to produce a series of activated intermediates that are able to destabilize the finely dispersed particles present in the water to be treated. The destabilized particles then aggregate to form flocs as outlined below.

(i) When aluminum is used as electrode, the reactions are as follows:

At the cathode : \(2H_2O + 2e^- \rightarrow H_2(g) + 2OH^-\)  \hspace{1cm} (1)

At the anode : \(Al \rightarrow Al^{3+} + 3e^-\) \hspace{1cm} (1a)
In the solution: \[
\text{Al}^{3+} (aq) + 3\text{H}_2\text{O} \rightarrow \text{Al(OH)}_3 + 3\text{H}^+ (aq) \quad (1b)
\]
\[
n\text{Al(OH)}_3 \rightarrow \text{Al}_n(\text{OH})_{3n} \quad (1c)
\]

(ii) When magnesium is used as the electrode, the reactions are as follows:

At the anode: \[
\text{Mg} \rightarrow \text{Mg}^{2+} + 2e^- \quad (2)
\]

In the solution: \[
\text{Mg}^{2+} (aq) + 2\text{H}_2\text{O} \rightarrow \text{Mg(OH)}_2 + 2\text{H}^+ (aq) \quad (2a)
\]
\[
n\text{Mg(OH)}_2 \rightarrow \text{Mg}_n(\text{OH})_{2n} \quad (2b)
\]

The advantages of electrocoagulation include high particulate removal efficiency, a compact treatment facility, relatively low cost, and the possibility of complete automation. This method is characterized by reduced sludge production, a minimum requirement of chemicals and ease of operation [29–31].

In general, direct current (DC) is used in an electrocoagulation processes. In this case, an impermeable oxide layer may form on the cathode as well as corrosion formation on the anode due to oxidation. These prevent the effective current transport between the anode and cathode, so the efficiency of electrocoagulation processes declines. These disadvantages of DC have been overcome by adopting alternating current (AC) in electrocoagulation processes. The main objective of this study is to investigate the effect of AC on the removal efficiency of cadmium using aluminum alloy as anode and cathode. The effect of the initial concentration of cadmium ion, pH, temperature, current density and coexisting ions were investigated. The adsorption kinetics of cadmium ions on aluminum hydroxide is also studied. For this, equilibrium adsorption behaviour is analyzed by fitting the Langmuir and Freundlich isotherm models. The adsorption kinetics of electrocoagulation was analyzed using first, second order kinetic models. Finally, the effects of temperature were studied to determine the nature of adsorption.

2. Materials and methods

2.1. Cell construction and electrolysis

Fig. 1 shows the electrolytic cell consisting of a 1.0-L Plexiglas vessel that was fitted with a polycarbonate cell cover with slots to introduce the anode, cathode, pH sensor, a thermometer and electrolytes. Aluminum alloy consisting of Zn (1–4%), In (0.006–0.025%), Fe (0.15%), Si (0–15%) (CSIR-CECRI, India), with a surface area of 0.2 dm² acted as the anode and cathode, respectively and placed at an interelectrode distance of 0.005 m. The temperature of the electrolyte has been controlled to the desired value with a variation of ±2 K by adjusting the rate of flow of thermostatically controlled water through an external glass-cooling spiral. A regulated direct current (DC) was supplied from a rectifier (10 A, 0–25 V; Aplab model) and regulated alternating current (AC) was supplied from a source (0–5 A, 0–270 V, 50 Hz; AMETEK Model: EC1000S).

Cadmium nitrate \(\text{Cd(NO}_3)_2 \cdot 4\text{H}_2\text{O}\) (Analar Reagent) was dissolved in tap (drinking) water for the required concentration. In all the experiments 20 mg/L of cadmium was used. The pH of the electrolyte was adjusted, if required, with HCl (1 mol/L) or NaOH (1 mol/L) solutions before adsorption experiments. To study the effect of co-existing ions, in the removal of cadmium, sodium salts (Analar Grade, Merck, Germany) of phosphate (0–50 mg/L), silicate (0–15 mg/L), carbonate (0–250 mg/L) and arsenic (0–5.0 mg/L) was added to the electrolyte.

![Fig. 1. Laboratory scale cell assembly. (1) DC power supply; (2) pH meter; (3) electrolytic cell; (4) cathode; (5) anode; (6) electrolyte; (7) outer jacket; (8) inlets for thermostatic water; (9) outlet for thermostatic water; (10) magnetic stirrer.](image)

2.2. Analytical method

The concentration of cadmium was determined using UV-visible Spectrophotometer with cadmium kits (MERCK, Pharo 300, Germany). The SEM and EDAX of cadmium adsorbed aluminum hydroxide coagulant were analyzed with a Scanning Electron Microscope (SEM) made by Hitachi (model s-3000h). The Fourier transform infrared spectrum of aluminum hydroxide was obtained using Nexus 670 FTIR spectrometer made by Thermo Electron Corporation, USA. The XRD for aluminum hydroxide coagulant was analyzed by X-ray diffractometer made by JEOL X-ray diffractometer (type – JEOL Japan). The concentration of carbonate, silicate, arsenic and phosphate were determined using UV-Visible Spectrophotometer (MERCK, Pharo 300).

3. Results and discussion

3.1. Effect of current density

The amount of cadmium removal depends upon the quantity of adsorbent (aluminum hydroxide) generated, which is related to the time and current density. The amount of adsorbent \([\text{Al(OH)}_3]\) was determined from the Faraday law

\[
E_c = \frac{ltM}{ZF}
\]

where \(I\) is the current in (A), \(t\) is the time (s), \(M\) is the molecular weight, \(Z\) is the electron involved, and \(F\) is the faraday constant (96485.3 C/mol). To investigate the effect of current density on the cadmium removal, a series of experiments were carried out by solutions containing constant cadmium loading of 20 mg/L, at a pH 7.0, with current density being varied from 0.1 to 0.5 A/dm² using both AC and DC current source. The results are presented in Table 1. The results show that the removal efficiency of cadmium was higher and energy consumption was lower in the case of AC than DC. This may be due to the uniform dissolution of anode and cathode during electrocoagulation in the case of AC. The removal efficiency was found showing the amount of cadmium adsorption increases with the increase in adsorbent concentration, which indicates that
the adsorption depends up on the availability of binding sites for cadmium.

3.2. Effect of pH

The adsorption behaviour of cadmium has been investigated at different pH values ranging from 4.0 to 9.0 using AC and DC source. The percentage of cadmium adsorption increased with increasing pH 7, a decreasing trend in adsorption was observed when below and above pH 7 for both AC and DC source. At an initial concentration of 20 mg/L, maximum adsorption of 97.5% and 96.2% at pH 7 for AC and DC source (Fig. 2). According to the literature pH of precipitation of cadmium starts at pH 8.2 [32], so in higher pH removal efficiency was low. At low pH, Cd²⁺ ions had to compete with H⁺ ions for adsorption sites on the adsorbent surface. As the pH increased, this competition weakens and more Cd²⁺ ions were able to replace H⁺ ions bound to the adsorbent surface.

3.3. Effect of initial cadmium concentration

To study the effect of initial concentration, experiments were conducted at varying initial concentrations from 10 to 50 mg/L using AC and DC. The removal of Cd(II) increased with time to obtain equilibrium at about 30 min (Fig. 3). The amount of cadmium adsorbed (qe) increased from 6.42 to 49.61 mg/g as the concentration was increased from 10 to 50 mg/L for the AC source. The figure also shows that the adsorption is the rapid in the initial stages and gradually decreases with progress of adsorption this is because of the great number of sites available for the sorption operation and adsorption equilibrium were then gradually achieved. The plots are single, smooth and continuous curves leading to saturation, suggesting the possible monolayer coverage to cadmium on the surface of the adsorbent [33]. In the case of DC the equilibrium time was found to be 45 min for all concentration studied (figure not shown).

3.4. Adsorption kinetics

The kinetics of removal of cadmium is explicitly explained in the literature using first-order and second-order kinetic models. The adsorption of cadmium is analyzed using Lagergran rate equation. The first order Lagergran model is [34,35],

\[ \frac{dq}{dt} = k_1(q_e - q_t) \]  

where, \( q_t \) is the amount of cadmium adsorbed on the adsorbent at time \( t \) (min) and \( k_1 \) (1/min) is the rate constant of first order adsorption. The integrated form of the above equation with the boundary conditions \( t = 0 \) to \( q = 0 \) to \( q \) and then rearranged to obtain the following time dependence function,

\[ \frac{\log(q_e - q_t)}{\log(q_e)} = \frac{k_1}{2.303} \]  

where \( q_e \) is the amount of cadmium adsorbed at equilibrium. The \( q_e \) and rate constant \( k_1 \) were calculated from the slope of the plots of \( \log(q_e - q_t) \) versus time \( t \) (figure not shown). It was found that the calculated \( q_e \) value do not agrees with the experimental \( q_e \) values.

The second order kinetic model is expressed as [36]

\[ \frac{dq}{dt} = k_2(q_e - q_t)^2 \]  

where \( k_2 \) is the rate constant of second order adsorption. The integrated form of Eq. (6) with the boundary condition \( t = 0 \) to \( q = 0 \) to \( q \) is

\[ \frac{1}{(q_e - q_t)} = \frac{1}{q_e} + k_2t \]

Eq. (7) can be rearranged and linearized as,

\[
\frac{t}{q_t} = \frac{1}{k_2q_e^2} + \frac{t}{q_e}
\]

(8)

The plot \( t/q_t \) versus time (t) (Fig. 4) shows the straight line. The second order kinetic values of \( q_e \) and \( k_2 \) were calculated from the slope and intercept of the plots \( t/q_t \) versus t. Table 2 depicts the computed results obtained from first and second order kinetic model for AC and DC source. The calculated \( q_e \) values well agree with the experimental \( q_e \) values for second order kinetics model better than the first order kinetics model for both AC and DC. These results indicate that the adsorption system belongs to the second order kinetic model.

3.5. Adsorption isotherm

The adsorption capacity of the adsorbent has been tested using Freundlich and Langmuir isotherm and Dubinin–Radushkevich isotherms. To determine the isotherms, the initial pH was kept at 7 and the concentration of cadmium used was in the range of 10–50 mg/L.

3.5.1. Freundlich isotherm

The Freundlich isotherm is an empirical model relates the adsorption intensity of the sorbent towards adsorbent. The isotherm is adopted to describe reversible adsorption and not restricted to monolayer formation. The mathematical expression of the Freundlich model can be written as [37]

\[
q_e = Kc^n
\]

(9)

Fig. 4. Second order kinetic model plot of different concentrations of cadmium. Conditions: current density of 0.2 A/dm²; temperature of 303 K; pH of 7.0.

Eq. (9) can be linearized in logarithmic form and the Freundlich constants can be determined as follows [38]

\[
\log q_e = \log k_f + n \log C_e
\]

(10)

where, \( k_f \) is the Freundlich constant related to adsorption capacity, \( n \) is the energy or intensity of adsorption, \( C_e \) is the equilibrium concentration of cadmium. To determine the isotherms, the cadmium concentration used was 10–50 mg/L and at an initial pH 7. The Freundlich constants \( k_f \) and \( n \) values were shown in Table 3 for AC and DC source. It has been reported that values of \( n \) lying between 0 and 1 indicate favorable adsorption. From the analysis of the results it is found that the Freundlich plots fit satisfactorily with the experimental data obtained in the present study.

3.5.2. Langmuir isotherm

The Langmuir isotherm is a valid monolayer sorption on a surface containing a finite number of binding sites. It assumes uniform energies of sorption on the surface and no transmigration of sorbate in the plane of the surface.

The linearized form of Langmuir adsorption isotherm model is [39]

\[
\frac{C_e}{q_e} = \frac{1}{q_m b} + \frac{C_e}{q_m}
\]

(11)

where \( C_e \) is the concentration of the cadmium solution (mg/L) at equilibrium, \( q_e \) is the adsorption capacity (Langmuir constant) and \( b \) is the energy of adsorption. Fig. 5 shows the Langmuir plot with experimental data. Langmuir plot is a better fit with the experimental data compare to Freundlich plots. The value of the adsorption capacity \( q_m \) as found to be 526.33 mg/g and 501.22 mg/g for AC and DC source which is higher than that of other adsorbents studied. The essential characteristics of the Langmuir isotherm can be expressed as the dimensionless constant \( R_L \) [40]

\[
R_L = \frac{1}{1 + bC_0}
\]

(12)

where $R_t$ is the equilibrium constant it indicates the type of adsorption, $b, C_o$ is the Langmuir constant. The $R_t$ values between 0 and 1 indicate the favorable adsorption.

### 3.5.3. Dubinin–Radushkevich (D–R) isotherm

Dubinin and Radushkevich have proposed another isotherm which can be used to analyze the equilibrium data. It is not based on the assumption of homogeneous surface or constant adsorption potential, but it is applied to estimate the mean free energy of adsorption ($E$). This model is given by

$$q_e = q_m e^{-B e^{-E}}$$

(13)

where $e$ is Polanyi potential, equal to $RT \ln(1 + 1/C_o)$, $B$ is related to the free energy of sorption and $q_m$ is the Dubinin–Radushkevich (D–R) isotherm constant [41]. The linearized form is

$$\ln q_e = \ln q_m - 2B RT \ln \left[1 + \frac{1}{C_o}\right]$$

(14)

The isotherm constants of $q_m$ and $B$ are obtained from the intercept and slope of the plot of $\ln q_e$ versus $e^2$ [42]. The constant $B$ gives the mean free energy of adsorption per molecule of the adsorbate when it is transferred from the solid from infinity in the solution and the relation is given as

$$E = \frac{1}{\sqrt{2B}}$$

(15)

The magnitude of $E$ is useful for estimating the type of adsorption process. It was found to be 7.32 and 5.22 kJ/mol for AC and DC, which is smaller than the energy range of adsorption reaction, 8–16 kJ/mol [43]. So the type of adsorption of cadmium on aluminum alloy was defined as chemical adsorption.

The correlation co-efficient values of different isotherm models are listed in Table 3. The Langmuir isotherm model has higher regression co-efficient ($R^2 = 0.999$) when compared to the other models. The adsorption data show good fit to the Langmuir then Freundlich and D–R adsorption isotherm as depicted by the regression coefficient for these systems for both AC and DC. $R_t$ values between 0 and 1.0 further indicate a favorable adsorption of cadmium.

### 3.6. Effect of temperature

To study the temperature effect, the initial pH was kept at 7 and the concentration of cadmium used was in the range of 10–50 mg/L for both AC and DC. The amount of cadmium adsorbed on the adsorbent increases by increasing the temperature indicating the process to be endothermic. The diffusion co-efficient ($D$) for intraparticle transport of cadmium species into the adsorbent particles has been calculated at different temperature by

$$t_{1/2} = \frac{0.03 \times r_o^2}{D}$$

(16)

where $t_{1/2}$ is the time of half adsorption ($s$), $r_o$ is the radius of the adsorbent particle (cm), $D$ is the diffusion co-efficient in cm$^2$/s. For all chemisorption system the diffusivity co-efficient should be $10^{-5}$–$10^{-13}$ cm$^2$/s [44]. In the present work, $D$ is found to be in the range of $10^{-9}$ cm$^2$/s. The pore diffusion coefficient ($D$) values for various temperatures and different initial concentrations of cadmium are presented in Table 4, respectively.

To find out the energy of activation for adsorption of cadmium, the second order rate constant is expressed in Arrhenius form [45].

$$\ln k_2 = \ln k_o - \frac{E}{RT}$$

(17)

where $k_o$ is the constant of the equation (g/mg min), $E$ is the energy of activation (J/mol), $R$ is the gas constant (8.314 J/mol K) and $T$ is the temperature in K. Fig. 6 shows that the rate constants vary with temperature according to Eq. (17). The activation energy (0.954 (kJ/mol for AC and 0.662 (kJ/mol for DC source, respectively) is calculated from slope of the fitted equation. The free energy change is obtained using the following relationship:

$$\Delta G = -RT \ln K_e$$

(18)

![Fig. 5. Langmuir plot (1/C_e versus 1/q_e). Conditions: pH of 7.0; current density: 0.2 A/dm$^2$; temperature of 303 K; concentration of 10–50 mg/L.](image)

![Fig. 6. Plot of log$k_2$ and 1/T. Conditions: pH of 7.0; current density of 0.2 A/dm$^2$; temperature of 303 K; concentration of 10–50 mg/L.](image)

Table 4 Pore diffusion coefficients for the adsorption of cadmium at various concentration and temperature.
where $\Delta G$ is the free energy (kJ/mol), $K_c$ is the equilibrium constant, $R$ is the gas constant and $T$ is the temperature in K. The $K_c$ and $\Delta G$ values are presented in Table 5. From the table it is found that the negative value of $\Delta G$ indicates the spontaneous nature of adsorption.

Other thermodynamic parameters such as entropy change ($\Delta S$) and enthalpy change ($\Delta H$) were determined using van’t Hoff equation,

$$\ln K_c = \frac{\Delta S}{R} - \frac{\Delta H}{RT}$$

(19)

The enthalpy change and entropy change were obtained from the slope and intercept of the van’t Hoff linear plots of $\ln K_c$ versus $1/T$ (Fig. 7). A positive value of enthalpy change ($\Delta H$) indicates that the adsorption process is endothermic in nature, and the negative value of change in internal energy ($\Delta G$) show the spontaneous adsorption of cadmium on the adsorbent. Positive values of entropy change show the increased randomness of the solution interface during the adsorption of cadmium on the adsorbent. Enhancement of adsorption capacity of electro coagulant (aluminum hydroxide) at higher temperatures may be attributed to the enlargement of pore size and or activation of the adsorbent surface. Using Lagergrain rate equation, first order rate constants and correlation co-efficient were calculated for different temperatures (313–343 K). The calculated 'q_e' values obtained from the first order kinetics agrees with the experimental 'q_e' values better than the Second order kinetics model. Table 6 depicts the computed results obtained from first and second order kinetic models. These results indicate that the adsorption follows first order kinetic model at different temperatures used in this study.

3.7. Effect of coexisting ions

To study the effect of co-existing ions, in the removal of cadmium, sodium salts of carbonate (0–250 mg/L), phosphate (0–50 mg/L), silicate (0–15 mg/L), and arsenate (0–5.0 mg/L) was added to the electrolyte and electrolysis was carried out using AC with a initial pH of 7 at a temperature of 313 K.

3.7.1. Carbonate

Effect of carbonate ($HCO_3^-$) on cadmium removal was evaluated by increasing the $HCO_3^-$ concentration from 5 to 250 mg/L in the electrolyte. The removal efficiencies are 97.5, 80, 69.1, 30.2, and 16% for the $HCO_3^-$ ion concentration of 0, 5, 65, 150 and 250 mg/L, respectively. From the results it is found that the removal efficiency of the cadmium is not affected by the presence of $HCO_3^-$ below 5 mg/L. Significant reduction in removal efficiency was observed above 5 mg/L of $HCO_3^-$ concentration is due to the passivation of anode (resulting the hindering of the dissolution process of anode) and the presence of $HCO_3^-$ ion.

3.7.2. Phosphate

The concentration of phosphate ($H_2PO_4^-$ and $HPO_4^{2-}$) ion was increased from 5 to 50 mg/L, the contaminant range of $H_2PO_4^-$ and $HPO_4^{2-}$ in the ground water. The removal efficiency for cadmium was 97.5, 71.3, 52.6 and 43% for 0, 5, 25 and 50 mg/L of $H_2PO_4^-$ and $HPO_4^{2-}$ ion, respectively. There is no change in removal efficiency of cadmium below 5 mg/L of $H_2PO_4^-$ and $HPO_4^{2-}$ in the water. At higher concentrations (at and above 5 mg/L) of $H_2PO_4^-$ and $HPO_4^{2-}$, the removal efficiency decreases to 43%. This is due to the preferential adsorption of $H_2PO_4^-$ and $HPO_4^{2-}$ over cadmium as the concentration of $H_2PO_4^-$ and $HPO_4^{2-}$ increase.

3.7.3. Silicate

Effect of silicate on the removal efficiency of cadmium was investigated. The respective efficiencies for 0, 5, 10 and 15 mg/L of silicate are 97.5, 65, 46 and 19%. The removal of cadmium decreased with increasing silicate concentration from 0 to 15 mg/L. In addition to preferential adsorption, silicate can interact with aluminum hydroxide to form soluble and highly dispersed colloids that are not removed by normal filtration.

3.7.4. Arsenate

From the results it is found that the efficiency decreased from 97.5, 81.2, 70.2, 64 to 31% by increasing the concentration of arsenate ($H_2AsO_4^-$ and $HASO_4^{2-}$) from 0, 0.5,1.3 and 5 mg/L. Like phosphate ion, this is due to the preferential adsorption of $H_2AsO_4^-$ and $HASO_4^{2-}$ over cadmium as the concentration of $H_2AsO_4^-$ and $HASO_4^{2-}$ increases, So, when $H_2AsO_4^-$ and $HASO_4^{2-}$ ions present in the water are to be treated which compete greatly with cadmium ions for the binding sites.

3.8. A pilot plant study

A pilot plant capacity cell (Fig. 8) was designed, fabricated and operated for the removal of cadmium from water. The system consists of AC/DC power supply, an electrochemical reactor, a water tank, a feed pump, a flow control valve, a flow measuring unit, a circulation pump, settling tank, sludge collection tank, filtration unit provisions for gas outlet and treated water outlet. The reactor is made of PVC with an active volume of 2000 L. The aluminum

![Fig. 7. Plot of ln Kc and 1/T. Conditions: pH of 7.0: current density of 0.2 A/dm²; temperature of 303 K; concentration of 10–50 mg/L.](image-url)
alloy electrodes (anode and cathode) each consist of five pieces situated approximately 5 mm apart from each other and submerged in the solution. The total electrode surface area is 1500 cm² for both cathodes and anodes. The cell was operated at a current density of 0.2 A/dm² and the electrolyte pH of 7.0. The results showed that the removal efficiency of 97.5 and 96.2% with the energy consumption of 0.454 and 1.002 kWh kg⁻¹ was achieved at a current density of 0.2 A/dm² and pH of 7.0 using aluminum alloy as electrodes using AC and DC, respectively. The results were consistent with the results obtained from the laboratory scale, showing that the process was technologically feasible.

3.9. Surface characterization

3.9.1. SEM and EDAX characterization

In order to gain more insight into the effect of alternating current, the morphology of the electrode surface after two kinds of electrolysis (AC and DC) was characterized by SEM as shown in Fig. 9(a) and (b). It can be observed that when the AC was fed, less disordered pores formed and a smooth microstructure of aluminum suggesting the aluminum electrodes were dissolved uniformly during the electrolysis. While for the electrodes fed with DC, the electrode surface is found to be rough, with a number of dents. These dents are formed around the nucleus of the active sites where the electrode dissolution results in the production of aluminum hydroxides. The formation of a large number of dents may be attributed to the anode material consumption at active sites due to the generation of oxygen at its surface.

Energy-dispersive analysis of X-rays was used to analyze the elemental constituents of cadmium-adsorbed aluminum hydroxide (Fig. 10). It shows that the presence of cadmium, Al and O appears in the spectrum. EDAX analysis provides direct evidence that cadmium is adsorbed on aluminum hydroxide.

3.9.2. XRD studies

X-ray diffraction spectrum of aluminum electrode coagulant showed very broad and shallow diffraction peaks (Fig. 11). This broad humps and low intensity indicate that the coagulant is amorphous.

![Fig. 8. Flow diagram of the pilot plant electrocoagulation system. 1. AC/DC power supply, 2. electro coagulation cell, 3. water tank, 4. inlet pump, 5. flow meter, 6. gas outlet, 7. setting tank, 8. sludge collection tank, 9. filtration unit, 10. recirculation pump and 11. treated water.](image)

![Fig. 10. EDAX spectrum of cadmium-adsorbed aluminum hydroxide.](image)
or very poor crystalline in nature. It is reported [46] that the crystallization of aluminum hydroxide is a very slow process resulting all aluminum hydroxides found to be either amorphous or very poorly crystalline. The literature on the amorphous nature of aluminum oxide layer supported the present results [46].

3.9.3. FTIR studies

Fig. 12 presents the FT-IR spectrum of cadmium–aluminum hydroxide. The sharp and strong peak at 3444.38 cm⁻¹ is due to the O–H stretching vibration in the Al(OH)₃ structures. The 1633.92 cm⁻¹ peak indicates the bend vibration of H–O–H. The strong peak at 1038.48 cm⁻¹ is assigned to the Al–O–H bending. Cd–O vibration at 862.25 cm⁻¹ also observed.

4. Conclusion

The results showed that the optimized removal efficiency of 97.5% and 96.2% was achieved for AC and DC source at a current density of 0.2 A/dm² and pH of 7.0 using aluminum alloy as anode and cathode. The aluminum hydroxide generated in the cell remove the cadmium present in the water and to reduce the cadmium concentration to less than 0.005 mg/L, and made it for drinking. The results indicate that the process can be scaled up to higher capacity. For both AC and DC electrolysis the adsorption of cadmium preferably fitting Langmuir adsorption isotherm better than Freundlich isotherm. The adsorption process follows second order kinetics. Temperature studies showed that adsorption was endothermic and spontaneous in nature. From the surface characterization studies, it is confirmed that the aluminum hydroxide generated in the cell adsorbed cadmium present in the water.
