Structural, Optical, and Magnetic Properties of MgFe$_2$O$_4$ Synthesized with Addition of Copper

Angappan Sankaramahalingam and John Berchmans Lawrence

CSIR-Central Electrochemical Research Institute, Karaikudi, India

INTRODUCTION

Polycrystalline ferrites are optimal structural materials in high and very high frequency circuits, owing to their excellent electrical and magnetic properties. Moreover, they are more stable than other competing materials, and are able to fulfill a range of applications in radio frequency circuits, operating devices, transformer cores, high-quality filters, choke coils, data storage devices, noise filters, recording heads, antennae, read/write heads for high-speed digital tape, and coil cores. Many physical properties of ferrites depend on their microstructure, porosity, grain size, state of chemical order, and the cation distribution, and are also strongly connected with the preparative methods. Magnesium ferrite is a soft magnetic n-type semiconducting material that finds application in heterogeneous catalysis, sensors, photoelectrical, and magnetic technologies. The structural formula of magnesium ferrite is usually written as (Mg$_{2-x}$Fe$_x$$^{3+}$)[Mg$_x$$^{2+}$Fe$_{2-x}$$^{3+}$]O$_4$, where round and square brackets denote cation sites of tetrahedral (A) and octahedral [B] coordinations, respectively, and x represents the degree of inversion, which is defined as the fraction of the (A) sites occupied by Fe$^{3+}$ cations. Interesting physical and chemical properties of ferrospinel arise from their ability to distribute the cations among the tetrahedral (A) and octahedral [B] sites. Ladgaonkar and Vaingankar proposed that it is their structural, electrical, and magnetic properties of spinel that determine their applications in many fields. Sepelak et al. studied changes in the structure of MgFe$_2$O$_4$ caused by high-energy milling using X-ray diffraction (XRD). Rane et al. prepared MgFe$_2$O$_4$ from synthetic iron oxide obtained from chemically beneficiated iron ore rejects. The cation distribution occurs in such a way that there is not much change in the Fe$^{2+}$, in spite of the presence of Si, Al, and Mn as impurities. Magnesium ferrite belongs to a partially inverse spinel type, and can be considered as a collinear ferrimagnet whose degree of inversion depends on the thermal history of the sample. The kinetics of formation of MgFe$_2$O$_4$ was studied by Moustafa and Morsi. The structural and magnetic properties of MgFe$_2$O$_4$ were determined from transmission electron microscopy, XRD, Mössbauer spectroscopy, and magnetometry by Oliver et al. Narasimhan and Swamy explained interesting variations in cation distribution in solid solutions of composition MgAl$_{2-x}$Fe$_x$O$_4$ (x = 0 to 2). Although extensive studies have been performed on the influence of other cations on MgFe$_2$O$_4$, very limited information is available on the addition of Cu in the ferrite compound. This article reports the results of a study on the structural, optical, and magnetic properties of MgFe$_2$O$_4$ using XRD, IR absorption spectroscopy, UV-VIS-transmittance spectra, scanning electron microscopy, and Mössbauer studies.

EXPERIMENTAL

Magnesium ferrite was prepared by a solid-state reaction method using analytical grade MgO and Fe$_2$O$_3$ and Cu powder. 10 wt% of Cu was used. The mixture taken in stoichiometric proportions was thoroughly ground to obtain a fine blend, pre-sintered at 900°C for 24 h, and slowly cooled to room temperature. The pre-sintered powders were pelletized in a hydraulic press at 4 T/cm$^2$ to obtain 1 and 2.5 cm diameter pellets. Then the pellets were sintered at 700°C, 1000°C, and 1300°C for 70 h and furnace-cooled.
XRD analysis of the ferrite samples were carried out with a JEOL XRD unit (Model 8030) using CuKα radiation (λ = 1.54 Å). FTIR spectra of the samples were recorded in the range of 400–1000 cm⁻¹ in KBr using a Perkin-Elmer IR spectrometer. UV-transmittance curves were also made using a Varian Carry 500 Scan UV-VIS-NIR spectrophotometer. Microstructural features were examined using a HITACHI S-3000H Scanning Electron Microscope. Mössbauer spectral measurements were carried out at 298K under an external magnetic field applied perpendicular to the γ-ray direction using a 57Co/Rh γ-ray source. The velocity scale was calibrated relative to 57Fe in Rh.

RESULTS AND DISCUSSIONS

X-Ray Diffraction

Figure 1 shows the XRD patterns of MgFe₂O₄ with and without Cu prepared by sintering at 1300°C. The patterns reveal the formation of a single-phase cubic spinel. From the data, the lattice parameter (a), X-ray density (Dₓ), structure factor F(θ), and oxygen ion positional parameter (u) were calculated and are presented in Table 1. The lattice parameter a is calculated from the following relation:

\[ a = d \sqrt{h^2 + k^2 + l^2} \]  [1]

where d is the interplanar distance for the plane hkl. The lattice parameter a increases with the addition of copper ions, which is attributed to the replacement of smaller Fe³⁺ (0.64 Å) ions by larger Mg²⁺ ions (0.66 Å). A similar behavior was reported for Ti-substituted Ni₀.₃Zn₀.₇Fe₂O₄, which is neither a complete normal nor an inverse spinel.[19] The same trend was reported for Ca-substituted MgFe₂O₄; it is found that a maximum of 23% of Ca²⁺ can be substituted for Mg²⁺.[20]

The X-ray density (Dₓ) was calculated using the following formula:

\[ Dₓ = \frac{8M}{N_a a^3} \]  [2]

where M is the molecular weight of the spinel, N is the Avogadro number, and a is the lattice parameter. The X-ray density decreases with the addition of copper content. This can be ascribed to the density and atomic weight of magnesium (1.74 g/cm³, 24.31 amu), which are lower than those of iron (7.87 g/cm³, 55.85 amu) and copper (8.93 g/cm³, 63.55 amu). The structure factor is a function of oxygen ion positional parameter and distribution parameter (y). The formula for the structure factor for the planes (hkl) are given by Furuhashi et al.[21] The formulae for the multiplicity factor and Lorentz polarization factor are taken from the literature.[22] The oxygen ion positional parameter is calculated by the following equation[23]:

\[ u = \left( \frac{r_A + R_0}{3a} \right) \left[ \frac{1}{3a} + \frac{1}{4} \right] \]  [3]

From the values it is observed that the lattice parameter and the structure factor are found to increase with the addition of Cu in MgFe₂O₄, whereas the X-ray density is found to decrease. The oxygen ion parameter has been found to be equal in both cases. In both cases, the higher octahedral energy for Mg²⁺ ions in comparison to that of Fe³⁺ ions coupled with low oxygen parameter (0.381) accounts for the inverse structure. It may be noted that the oxygen positional parameter is a qualitative measure of the size of tetrahedral sites.[18] The values of oxygen positional parameter for both compounds (0.431) reflect the presence of the same quantity of Mg²⁺ ions at the tetrahedral sites. The values are higher than the reported value (0.381), indicating that the compounds show some deviation from the ideal spinel ferrite. It is due to a gradual increase in Mg²⁺ ions in the tetrahedral sites.[18] In order to determine cation distribution, X-ray intensities were calculated using the following
is caused by stretching of tetrahedral cation and oxygen bonding, while \( \nu_2 \) is ascribed to vibrations of oxygen in a direction perpendicular to the axis joining the tetrahedral ion and oxygen. According to Patil et al.\[30\] band \( \nu_1 \) originates from intrinsic vibrations of the tetrahedral complexes corresponding to the highest restoring force, while band \( \nu_2 \) starts from intrinsic bond-bending vibrations of octahedral complexes. It can be seen from the spectra that \( \nu_1 > \nu_2 \). Furthermore, the absorption bands for the ferrites are found to be in the expected range. The difference in the band positions is due to difference in the Fe\(^{3+} - O\(^2-\) distance in the octahedral and tetrahedral configurations.\[31\] A third band (\( \nu_3 \)) in the spectra is attributed to an Mg\(^{2+} - O\(^2-\) complex at the octahedral site. The frequency of band \( \nu_4 \) depends on the mass of the tetrahedral metal ion complex and hence it is responsible for lattice vibrations of ions at the tetrahedral site. Srivastava and Srinivasan\[32\] stated that the bond stretching for Cu-added MgFe\(_2\)O\(_4\) synthesised at 1000°C. Splitting of \( \nu_1 \) and \( \nu_2 \) into shoulders is not observed for Cu-added MgFe\(_2\)O\(_4\) at 700°C, which also confirms the absence of excess Fe\(^{3+}\) ions.

\[ I_{hkl} = |F_{hkl}|^2 PL_p \]  \[ 4 \]

The distribution of divalent and trivalent cations among tetrahedral and octahedral sites in both ferrite samples are determined from the ratio of intensities of X-ray diffraction lines I\(_{220}/I_{1440}\) and I\(_{422}/I_{400}\).\[25\] The intensity of 220 and 422 planes are mostly sensitive to cations on tetrahedral sites\[26, 27\] and that of 400 planes to the cations in the octahedral sites.\[26\] The intensity of 220 and 422 planes increase with the addition of Cu. The bond lengths between the cations (Me-Me), and anions (Me-O) were calculated using the following relations, and the values are presented in Table 2.

\[ d_t = a \sqrt{3} (u - 0.125) \]  \[ 5 \]
\[ d_0 = a \sqrt{3} (3u - 2u + 0.375) \]  \[ 6 \]
\[ r_t = d_t - r_0 \]  \[ 7 \]
\[ r_0 = d_0 - r_0 \]  \[ 8 \]

where \( r_t \) and \( r_o \) are the radii of the tetrahedral and octahedral intensities, and \( d_t \) and \( d_0 \) are the distances between a cation and its nearest anion\[28, 29\] and the radius of the tetrahedral and octahedral sites in both ferrite samples are determined.

From the table, it is seen that the Me-O and Me-Me bond lengths increase with the addition of Cu. The increase in Me-O and Me-Me bond lengths may be due to the occupancy of increasing amounts of Mg\(^{2+}\) ions in the A-site. The increase in Me-O and Me-Me distances may enhance the strength of magnetic interactions on the replacement of magnetic Fe\(^{3+}\) ions by non-magnetic Mg\(^{2+}\) ions.

**FTIR**

Figure 2 shows the FTIR spectra of the pure MgFe\(_2\)O\(_4\) and Cu-added MgFe\(_2\)O\(_4\). All the samples show two prominent absorption bands \( \nu_1 \) and \( \nu_2 \) in the range 540 to 460 cm\(^{-1}\). Band \( \nu_1 \) is caused by stretching of tetrahedral cation and oxygen bonding, while \( \nu_2 \) is ascribed to vibrations of oxygen in a direction perpendicular to the axis joining the tetrahedral ion and oxygen. According to Patil et al.\[30\] band \( \nu_1 \) originates from intrinsic vibrations of the tetrahedral complexes corresponding to the highest restoring force, while band \( \nu_2 \) starts from intrinsic bond-bending vibrations of octahedral complexes. It can be seen from the spectra that \( \nu_1 > \nu_2 \). Furthermore, the absorption bands for the ferrites are found to be in the expected range. The difference in the band positions is due to difference in the Fe\(^{3+} - O\(^2-\) distance in the octahedral and tetrahedral configurations.\[31\] A third band (\( \nu_3 \)) in the spectra is attributed to an Mg\(^{2+} - O\(^2-\) complex at the octahedral site. The frequency of band \( \nu_4 \) depends on the mass of the tetrahedral metal ion complex and hence it is responsible for lattice vibrations of ions at the tetrahedral site. Srivastava and Srinivasan\[32\] stated that the bond stretching for tetrahedral sites would lead to a higher force constant than that for the octahedral site. The shoulders \( \nu_{1-} \) and \( \nu_{1+} \) at 476 cm\(^{-1}\) and 449 cm\(^{-1}\), respectively, are assigned to Mg\(^{2+} - O\(^2-\) bond in Cu-added MgFe\(_2\)O\(_4\) synthesised at 1000°C. Splitting of \( \nu_1 \) and \( \nu_2 \) into shoulders is not observed for Cu-added MgFe\(_2\)O\(_4\) at 700°C, which also confirms the absence of excess Fe\(^{3+}\) ions.

\[ I_{hkl} = |F_{hkl}|^2 PL_p \]  \[ 4 \]
Similar results have also been reported by Shaikh et al.\cite{Shaikh} in the case of Li-Zn-Zr system.

The molecular weights of tetrahedral site (m_t) and octahedral site (m_o) were calculated using cation distribution:

\[
\left(\text{Mg}_{2+0.44}^{+} \text{Fe}_{0.56}^{3+}\right)[\text{Mg}_{0.56}^{2+} \text{Fe}_{1.44}^{3+}]\text{O}_4
\]

Cation distribution in the MgFe\textsubscript{2}O\textsubscript{4} from X-ray intensity calculations is required for the estimation of the force constants.\cite{34, 35} The force constants of tetrahedral site (k_t) and octahedral site (k_o) were calculated from IR absorption data using the following relations.

\[
K_t = 0.04415\nu_1^2 M_2 \left[ \frac{V}{V + 3} \right] \quad [18]
\]

\[
K_o = \frac{0.942128\nu_2^2}{(M_1 + 32)} \quad [19]
\]

Here \(V = \frac{64.2 M_{\text{tot}}}{M_2}\) and \(U = \frac{2 K_o}{(\nu_1^2 M_1 - 2 K_o)}\) where M\(_1\) and M\(_2\) are the molecular weights of the cations on A- and B-sites, respectively. Table 3 summarizes the values of \(\nu_1\), \(\nu_2\), \(k_t\), and \(k_o\) for the samples of MgFe\textsubscript{2}O\textsubscript{4} with and without addition of Cu. From the table it is observed that the force constants \(k_t\) and \(k_o\) increase with the addition of Cu as well as with sintering temperature.

**UV Transmittance**

The UV-transmittance spectra of the samples were recorded in the wavelength range 200 < \(\lambda\) < 1000 nm, and are presented in Figure 3. The values of absorbance, band edge, and fundamental absorbance edge derived from the figure are presented in Table 4. The fundamental absorption edge (FAE) decreases with the addition of Cu and increases with sintering temperature. This shift in the band edge energy is ascribed to the distortion of the band by lattice interaction.\cite{36} From the linear part of the curve, the extrapolated optical band gap, \(E_g\), for \(\alpha = 0\) for each curve was calculated using the following equation:

\[
E_g = \frac{1.24}{\lambda} \quad [20]
\]

It is found that the band edge (eV) increases with addition of Cu and also with the increase in sintering temperature. As a result, the band edges shifted from 2.40 to 2.74. For wavelengths above 800 nm, the transmittance of the sample is found to be constant. The percentage transmittance is found to be influenced by the addition of Cu and also by the sintering temperature. It is seen that the FAE decreases with the addition of Cu and also by the sintering temperature, except at 484 nm.

Scanning Electron Microscopy

Figure 4 shows the SEM microstructures of MgFe$_2$O$_4$ with and without Cu prepared at various sintering temperatures (700, 1000, and 1300°C). The micrographs show that the morphology of the compound is highly influenced by the addition of Cu. The parent compound shows a fine structure with faceted crystallites leaving behind many residual pores. The presence of voids is due to the migration of vacancies from the pore or the neck of the grain boundary. The crystallites are spherical in shape. (Figure 4). Figure 4 reveals the highly dispersed nature of the particles, which appear to aggregate. The duplex structure is formed during the sintering process, with small grain bridges forming around large crystallites. The smaller grains imply that a large number of insulating grain boundaries act as barriers to the flow of electrons. Figure 4 shows the morphology of the sintered Cu-added MgFe$_2$O$_4$ at 1000°C. The microstructure has a significantly finer grain size, suggesting that the diffusion was impeded when the two phases were well mixed. Figure 4 shows a dense, and homogenous surface with little pores. The average grain size and grain growth seem to have increased with sintering temperature.

FIG. 4. SEM images of (a) MgFe$_2$O$_4$; and MgFe$_2$O$_4$ + 10 wt% Cu sintered at (b) 700°C, (c) 1000°C, and (d) 1300°C.
 FIG. 5. Room temperature Mössbauer spectra of (a) MgFe$_2$O$_4$ and (b) MgFe$_2$O$_4$ + 10 wt% Cu samples sintered at 1000 °C.

Mössbauer Spectrum

Room-temperature Mössbauer measurements performed on 1000 °C sintered MgFe$_2$O$_4$ with and without copper are shown in Figure 5. The spectra show two sextets and one doublet absorption. The sextet indicates a magnetic site, while the doublet shows a non-magnetic site. The spectral lines also reveal a partial collapse of the magnetic hyperfine splitting and the appearance of a central doublet (Figure 5). The doublet can be understood to arise from $^{57}$Fe in ultrafine ferrite particles exhibiting super-paramagnetic behavior.$^{[37, 38]}$ The room-temperature Mössbauer spectrum of MgFe$_2$O$_4$ was taken at zero applied magnetic field, which indicates that there is a particle overlap of the (A) and [B] sub-spectra due to the smaller difference between the hyperfine fields of the iron atoms in the two sub-lattices. The almost complete resolution of the patterns in the case of MgFe$_2$O$_4$ is due to octahedrally and tetrahedrally coordinated Fe$^{3+}$ ions. The hyperfine parameters of MgFe$_2$O$_4$ and Cu-added MgFe$_2$O$_4$ sintered at 1000 °C are presented in Table 5.

The general trend of increase in the hyperfine value is presumably due to the strengthening of A-B exchange interaction caused by Mg$^{2+}$ ions with Fe$^{3+}$ ions.$^{[39]}$ It also indicates that the isomer shifts and the magnetic hyperfine field values are consistent with the high spin Fe$^{3+}$ charge state.$^{[40]}$ The addition of copper increases the isomer shift values from 0.82 to 1.15, which indicates that the s-electron charge distribution of the Fe$^{3+}$ ions changes with the addition of Cu. As indicated, the samples exhibit typical relaxation spectra at room temperature and could be analyzed in terms of the superposition of two sextets and one quadrupole. For the exchange-coupled Fe$^{3+}$ ions in the octahedral sites, it appears that upon addition of Cu there is an overall increase in the hyperfine splitting value from 46.5 to 50.8 in the A-site and 50.1 to 60 in the B-site. This could be due to the relatively strong ferromagnetic exchange interaction with increasing number of Mg$^{2+}$ ions.$^{[39]}$ The degree of inversion, calculated from the sub-spectral area ratio, decreases with the addition of Cu. The sextet with the largest hyperfine field value of 50.1 and the largest center shift is assigned to the Fe$^{3+}$ ions at the B-sites and the sextet with the smallest hyperfine field value of 46.5 and the smallest center shift is assumed to arise from the Fe$^{3+}$ ions at A-sites.$^{[41]}$ Apart from the well-defined sextets, the Mössbauer spectra also consist of a super-paramagnetic doublet whose intensity increases as the particle size decreases. The quadruple splitting of this doublet also increases with the addition of Cu from 0.84 to 1.08. The sextet with the higher isomer shift (ISA) value of 0.82 and smaller hyperfine splitting (BhfA) value of 46.5 represents the A-site. The sextet with the lower isomer shift (ISB) value of 0.53 and largest hyperfine splitting (BhfB) value of 50.1 represents the B-site.$^{[42]}$ Thus, each sextet corresponds to Fe$^{3+}$ ions either in A- or B-sites within the fcc array of oxygen atoms.

The Mössbauer spectra of MgFe$_2$O$_4$ and Cu-added MgFe$_2$O$_4$ show a small (relative areas of 5% and 9% at the A-site and B-site, respectively) doublet as well as two sextets. Two sextets are observed in the Mössbauer spectra of the inverse spinels due to two environments for Fe$^{3+}$ ions (A-site and B-site), both of which are magnetic due to antiferromagnetic coupling between the two sites. For magnetically ordered spinel ferrites, the magnetic hyperfine field due to Fe at A-sites (BhfA) is

usually smaller (46.5, 50.8) than that of Fe at B-sites (B_{hf});
(50.1, 60) [43]. The hyperfine fields B_{hf} for the A- and B-sites are
determined from the separation between the centroids of the
peaks in each Zeeman pattern. The occupation numbers of the Fe^{3+}
ions can be considered proportional to the corresponding
areas of their Mössbauer spectra. Consequently, the relative
numbers of Fe^{3+} ions in the A- and B-sites are determined from
the ratios of the areas under the two sub-lattices [39].

CONCLUSIONS

The influence of Cu addition on the structural, optical and
magnetic properties of MgFe_{2}O_{4} has been investigated by using
XRD, IR absorption spectroscopy, transmittance spectroscopy,
SEM, and Mössbauer spectroscopy. The X-ray analysis con-
sirmed the single-phase cubic structure of the samples. The
lattice parameter and structure factor were found to increase
with the addition of Cu whereas the X-ray density was found
to decrease. The oxygen positional parameter has been found
to be equal in both the cases. The Me-O and Me-Me bond lengths
increase with the addition of Cu due to the increased occupancy
of Mg^{2+} ions in the A-site. IR spectral analysis confirms the
presence of Fe^{3+}, Mg^{2+} ions on both tetrahedral and octahedral
sites. The force constants k_{1} and k_{0} are found to increase with
the addition of Cu and with sintering temperature due to stretching
vibrations of the ions at the tetrahedral and octahedral sites. The
optical band gap has been found to increase with the addition of
Cu and also with an increase in sintering temperature, whereas
the fundamental absorption edge decreases due to the distor-
tion of the band by lattice interaction. The SEM features clearly
show that the morphology of the compound is highly influenced
by the addition of Cu. Mössbauer studies show an increase in
the hyperfine value with the addition of Cu, presumably due to a
strengthening of A-B exchange interaction caused by the Mg^{2+}
ions with Fe^{3+} ions. The addition of copper also increases the
isomer shift values and quadrupole splitting of the doublet.
